Abstract

Economic theory gives no clear indication of the minimum number of producers necessary for a market to define competitive price-quantity equilibria, which approximate price equal to marginal cost. Previous work and Federal Energy Regulatory Commission (FERC) guidelines generally suggest that 6–10 suppliers may be workably competitive. Our experiments with PowerWeb suggest that a higher number of suppliers may be necessary to approximate competitive market solutions, this in the absence of any communication among producers. As communications rules are altered to parallel differing types of antitrust enforcement, market results with 24 participants approach pure monopoly values.

JEL classification: Q4; L11; L94

1. Introduction

The early experience in the restructured power markets of California and PJM raised several issues. (PJM as a system includes Pennsylvania, New Jersey, MD, Virginia, the District of Colombia, and Delaware.) Issues of interest include price spikes, supplier outages, periodic unavailable capacity, brownouts, and the overall relationship of market clearing prices to marginal costs. Implicit in these subjects is the
possible exercise of market power by generators and merchant traders. In restructured markets, both types of supplier submit offers to sell specific quantities of electricity at specific prices. The least-cost combination of offers is selected by an independent system operator (ISO). The price paid to the supplier depends upon the type of auction system used.

Fig. 1 shows an offer supply curve for July 6, 1999, for PJM. This system used a last-accepted-offer auction, where the price (the lowest necessary to meet actual load) is uniformly paid to all suppliers. The $1000 per MWh price cap, a ceiling price, the maximum price allowed, was nearly attained 49 times in the summer of 1999.

In general, average (not marginal) production costs are substantially less than $100 per MWh. This value includes both variable running cost, and fixed costs with a normal return on investment.

In California, similar market results occurred in 2000 and early 2001 as shown in Fig. 2. Average prices in the summer of 2000 were nearly 500% higher than during the same months 1 and 2 years earlier. From January to April 2001, spot prices were around $300 per MWh, 10 times higher than year earlier values. Unexpected heat and lowered hydro-power capacity contributed to abnormally higher demand and lower supply in the summer of 2000. Still, market power was discussed as a possible factor.

In a typical power auction, an aggregate offer curve (AOC) meets fixed (or inelastic) quantity demanded, thus setting a market clearing price. The AOC is the sum of offers from suppliers, and is usually a convex function of quantity, as in the “hockey stick” shape of the AOC in Fig. 1. AOCs are generally parallel to marginal cost curves, with an increasing difference at the right side of the offer curve. In preparing their individual offers, suppliers...
are influenced by available capacity, forecast demand, and actual load demand quantities. Offers also reflect the cost for quantity supplied; individual suppliers may consider either or both variable running costs and long-run fixed costs.

Throughout the 1990s and into the beginning of this decade both experimentalists and policy makers generally believed that 6–10 comparably sized suppliers defined a workably competitive market. The Federal Energy Regulatory Commission (FERC) guidelines held this to be so, as well as the findings of Bernard, Mount, Green and Newberry, Joskow, and Andersson and Bergman.

However, Rudkevich et al. used a model adapted from Kemperer and Meyer to suggest that 30 equal-sized market participants bring equilibrium price to an acceptable level of 5% above marginal cost at the equilibrium.

In the economic literature on power markets, antitrust policy is not discussed. It is implicitly assumed that antitrust law prevents direct communication and cooperation among suppliers. In the United States, explicit agreements to support prices or restrict output are prohibited by the Sherman Act. It is informal behavior that traditionally has been difficult to interpret. Parallelism by different firms in setting offer curves for price and capacity offered to an ISO could be acceptable in the absence of any communication between firms.

However, it is well known to energy economists and the antitrust bar that strong incentives exist to

---

undermine informal parallel systems as well as explicit agreements. Assume a system which initially results in withheld capacity by suppliers, and offer curves significantly above marginal cost curves. An individual supplier can engage in strategic behavior: even if earning rent considerably above competitive outcomes, he can earn a still higher level of rent by a minor downward adjustment in his offer curve, and an increase in his offered capacity. As each individual supplier seeks maximum profit, the market equilibrium thereby produced moves closer to the competitive market solution. It is workably competitive. This logic supports the belief noted above that 6–10 suppliers will be sufficient for a workably competitive market.

According to one perspective, price caps (also known as reservation prices or price ceilings) can encourage parallel offers.\textsuperscript{16}

We define four categories of allowable communication among power market participants:

Category One Behavior: No communication of any kind is allowable between suppliers participating in an ISO-administered market.

Category Two Behavior: General discussion of policies, strategies, and philosophies is possible, but there can be no mention or discussion orally or in writing of any specific prices or capacity quantities to be offered or withheld.

Category Three Behavior: Prices, price offer curves, capacity offered and withheld can be explicitly discussed. However, no binding agreements or contracts may be made, nor can any redistribution of profit occur.

Category Four Behavior: Similar to Category Three, but binding enforceable agreements are allowed.

Category One is not applicable in any actual restructured market; but, as will be seen below, it is of experimental interest. However, Category Two has traditionally been the flexible boundary of antitrust law. Power traders can legally attend trade, professional, and academic meetings, and may use such phrases as “Supplier income would be enhanced if offers were higher for higher cost units”. But an actual $ per MWh price cannot be named. Someone may say, “Withholding capacity increases revenue to cover everyone’s long-run capital costs”, but they may not name a megawatts (MW) figure to offer or withhold.

Category Three communications are currently “just over the fence”; they are not generally allowable under antitrust law.\textsuperscript{17} Category Four is an illustration of actions that might be allowable in the presence of a reinterpretation of antitrust law. Taken together, the four categories define locations on a continuum of antitrust concern.

Our experimental work sought to illuminate these two questions: how many suppliers are necessary for competitive equilibria to be approximated, and how does antitrust policy affect outcomes?

2. Hypotheses and experimental design

From previous research, we developed the following hypotheses.

\textbf{H1.} Six suppliers in a market are sufficient to give results comparable to a competitive market.

\textbf{H2.} A market with 12 suppliers\textsuperscript{18} will be competitive.

\textbf{H3.} With 24 suppliers, a market will be competitive.

\textbf{H4.} A competitive market with 24 suppliers will remain competitive when allowable communication moves into the Category Two type, from Category One. Restated, the existing antitrust framework is sufficient to maintain competition with a large number of suppliers.\textsuperscript{19}

\textbf{H5.} Introducing Category Three communication with 24 suppliers will have cartel-like results; lower prices than pure monopoly, but higher prices than in competition.

\textsuperscript{16} Scherer, op. cit., p. 191.

\textsuperscript{17} In real markets, Categories Two and Three are not as neatly differentiated with respect to antitrust law. Example: two suppliers discuss and compare old offers, and these two are not major participants. This behavior would be difficult to place in either category.

\textsuperscript{18} In actual power markets, suppliers are both generators that produce energy, and power merchants that buy and resell energy. In these experiments, all suppliers are generators.

\textsuperscript{19} In each case for hypotheses H1–H4, the alternate hypothesis is that the results are not comparable to those in a competitive market.
H6. With Category Four communication, market results approximate the prices expected from a pure monopoly.

In the fall of 2001, we conducted six experiments to examine and test these hypotheses. We used a class of 24 Cornell University electrical engineering and economics graduate students in all experiments. Subjects were paid in direct proportion to the profits of their simulated firms and earned $110 on average for 8 hours of participation. Before the experiments took place, each participant went through a training exercise where they competed against five smart computer agents in a uniform price auction for 25 trading periods.

Our experiments were conducted using Power-Web, a web-based platform for performing economic experiments on electricity markets. Users interact with the platform through the Netscape browser; sample offer and results screens are included as an Appendix A.

Each participant plays the role of an electricity supplier who owns five blocks of generating capacity. The first block is 50 MW and operates at a cost of $20 per MW. The second block is 20 MW with a marginal cost of $40 per MW. The last three blocks are 10 MW each with marginal costs of $48, $50, and $52 per MW. In each trading period, the supplier incurs a fixed interest charge of $1200. At the beginning of each period, the suppliers see a forecast of the system load. Forecast load in each period was randomly generated using a uniform distribution within a band of 430–550 MW. Actual demand in each period was equal to forecast demand, plus a stochastic term within $\pm 20$ MW. (These parameters are for a group of six participants. Values are scaled proportionally for the other group sizes.)

In each period, the supplier submits offers to sell blocks of capacity at prices designated by the supplier. This offer curve is entered into a uniform price auction run by an ISO. The ceiling price (i.e. price cap) is $100 per MW. A stand-by charge of $5 per MW is incurred for each block offered, regardless of whether an offer is accepted. This stand-by charge is included to represent the opportunity cost of being available for a time period, foregoing sales in other markets, and delaying maintenance activities. The supplier can choose to shut down one or more of his generating unit blocks and avoid the associated stand-by cost.

The ISO selects the least expensive combination of offers to meet the system load. The market clearing price is equal to the last-accepted-offer and is paid to all successful offers. The uniform price auction is currently used in the PJM, New York, New England, and Australian wholesale markets and was used in the California market. If not enough capacity is submitted to meet load, the ISO randomly recalls blocks withdrawn from the auction. The supplier is charged $10 per MW for each recalled block and receives the market clearing price for all recalled capacity. A similar recall procedure has been used in the PJM market.

The six experiments are divided into two series. In the first series the number of suppliers in a market is varied; in the second series, different levels of information exchange are allowed in stages comparable to Categories One through Four. In the first series of three experiments, no communication was allowed between participants; Category One rules were enforced. Initially, four groups of six each (sessions denoted as 6A, 6B, 6C, and 6D) participated in 40 trading periods. In the second experiment, the 24 participants were divided into two groups of 12 each (12A and 12B). Finally, as the third experiment, all 24 subjects participated in a single market (24A). The second and third experiments consisted of 25 periods each.

This first sequence could be seen as representing a policy of separation of larger firms into smaller firms. It must be considered possible that prices with 24 suppliers could be lower if they had no prior experience with the successful exercise of market power.

In the second series of three experiments, all 24 subjects participated in the same market for 20 periods and each experiment began with a group discussion led by an experiment participant. The discussion was intended to be analogous to legal Category Two communication: a professional conference session moderated by an industry professional. The purpose

---

20 Available at www.pserc.cornell.edu/powerweb.

21 Professor Fred Aman (Indiana University School of Law) reports that in his early career in antitrust in the private sector, he performed just this kind of role. Personal communication, March 4, 2002.
of the discussion was to increase industry profits. In this fourth experiment (24C), the discussion was overseen by the lead author, who played the role of an antitrust consultant. No discussion was allowed that violated Category Two rules, which represent current US antitrust law. In particular, no direct reference could be made to specific offer prices or specific quantities submitted into the market.

The next two experiments represent cases in which antitrust policy becomes increasingly less restrictive. In the fifth experiment (24D), any discussion was allowed even if in violation of antitrust law. This reflects Category Three communication. However, participants were allowed to make verbal agreements, but without consequences for those who did not follow the agreements. The sixth experiment (24E) was identical to the fifth except an explicit binding agreement was allowed; this is Category Four, the suspension of antitrust policy.

The timing of the experiments was such that there was a gap of one and a half months between the two series of experiments. During this time the class of subjects participated in other electricity market experiments, which potentially affected the comparability between the two series of experiments discussed here. Therefore, to initiate the second series of experiments on communication, we conducted another session with 24 participants (24B) and Category One rules: no information exchange. As this experiment and our third experiment are identical in all respects except for timing, we consider both sessions with 24 participants and Category One rules to be the third experiment.

It should be emphasized that these experiments are undertaken with a group of 24 graduate students in electrical engineering and economics, in a seminar on restructured power markets. We have proposed to illuminate the potential for the exercise of market power by capable and motivated participants. The results, then, should not be seen as representative of some larger or more general population of participants who are unfamiliar with power markets.

3. Experimental results

Fig. 3 displays the mean market prices for the experiments. Since the number of periods differed among experiments, we used data from the last 20 periods of each experiment only. This truncation eliminates “learning” effects observed in one of the initial sessions with six suppliers. Table 1 shows the variability of realized prices within each group. For the four groups each with six suppliers, under Category One rules prohibiting any communication, the mean market price is $75 per MWh. Our results with
six participants are comparable to the results of Mount et al. (2001),22 who conducted these same experiments with regulators in the New York State Department of Public Service (mean price=$71.50), engineering and economics graduate students at the University of Illinois ($72.25), and a previous class of engineering and economics graduate students at Cornell University ($79.00).23 For comparison, the competitive price is the market clearing price if all suppliers submitted offers equal to the marginal operating cost plus stand-by cost for each block of generation. For all experiments the competitive price is approximately $54, and is represented by the blue bar in Fig. 3. In Experiment 2, there are now two groups of 12 each. Doubling the size of groups results in a lower mean price, a reduction of $7 per MWh.

If we make use of a representation of workable competition resulting in a price within 10% of the competitive price, this would give a benchmark of approximately $59.40 per MWh.25 Experiment 1 and 2 prices are statistically higher than this benchmark ($t_{exp1}=4.97$, $P=0.00$; $t_{exp2}=1.89$, $P=0.06$). Experiment 3 prices are higher but not significantly so ($t_{exp3}=1.36$, $P=0.12$).

The group discussions that took place in Experiments 4–6 were very engaging and fruitful. In Experiment 4, when participants were allowed only Category Two legally permissible discussion, participants used clever analogies to encourage others to make high price offers.26 In reality, executives from the observed price and the competitive price for each experiment. The $t$-ratios are the test statistics corresponding to hypotheses H1–H3. For Experiments 1–3, we reject the null hypothesis that the experimental price is the same as the competitive price.24

---

23 These mean values are rounded to nearest 25¢.

24 Throughout the paper we use a 10% significance level.

25 Apparently the Department of Justice and the Federal Trade Commission used a 5% margin in the early 1990s in their analyses of mergers. Rudkevich et al., op. cit., pp. 22–23.

26 One participant: “On our fishing trip we found we should just catch a couple of fish, but make sure that we keep the big fish and throw the little fish back”.
competing energy companies do interact personally and professionally and have the opportunity to discuss non-binding price strategies that could be tacitly exercised in the interest of higher long-run profits. The results in this experiment: a mean price of $86 per MWh.

Experiment 5 passes into Category Three Behavior, now prohibited by antitrust law. Participants were allowed to discuss anything, including specific prices in $ per MWh and capacity withholding in MW, but were only allowed to make a verbal, non-binding agreement. Specific offer and quantity submission strategies were the basis of an agreement. All participants agreed to submit offers of $50, $99.97, $99.98, $99.99, and $100 for blocks 1–5, respectively. Guidelines were established on how much capacity to submit given the load forecast.27 The offer strategy was generally adhered to although as expected (see above) some participants undercut suggested offer prices by a few cents and submitted all capacity into the market. This plan resulted in a mean price of $99.99.

In Experiment 6, with Category Four rules, participants were allowed to and did organize an enforceable agreement. The offer and quantity strategy was similar to that used in the previous experiment, although now the last offer submitted was set to $100, the next highest offer set to $99.99, the next highest offer (if applicable) set to $99.98, and the first block offered for $50. Block 5 was always withheld from the market and the first three blocks were always offered into the market. It was agreed that if the range of earnings among the 24 participants (actual cash payouts) were greater than 75 cents, total earnings would be divided equally among participants. The range of earnings was only 27 cents and so no action was taken to equalize earnings. The price for each period in the experiment was at the $100 cap.

Corresponding with hypotheses H4–H6, we tested whether the mean price under Categories Two, Three, and Four rules is statistically different than under Category One rules with the same group size. From the regression results, we estimated a 90% confidence interval around the mean price for 24 participants under Category One Behavior, resulting in an upper bound of $81.24.28 Prices under Categories Two, Three, and Four rules are all noticeably greater than this cut-off. As such, we reject H4 and fail to reject H5 and H6. Contrary to expectations for H4, allowing legally admissible discussion did result in a statistically higher market price. As hypothesized (H5 and H6), allowing Categories Three and Four communication did result in a statistically higher market price. The pure monopoly outcome was reached under Category Four rules.

### 4. Interpretation

The first three hypotheses are rejected. Neither the market size of six suppliers, nor 12, nor 24, give market results which approximate the results of a purely competitive market. Considering the benchmark of 10% above the competitive market price as an illustration of workably competitive markets, the first three experiments result in mean prices above the benchmark.29

The fourth hypothesis assumed that, with 24 suppliers, moving from Category One Behavior (no communications) to Category Two rules (representing current antitrust policy), the market would remain competitive. However, the resulting average of $86 is significantly different from the competitive price of $54.

$N=8$ is defined as the sum of group experimental sessions: four groups with six participants each, two groups with 12 participants each, and two sessions with the 24 participant group.

27 All participants seemed enthusiastic about the new rules. A comment: “All right! It sounds like we can make lots of money”.

28 In constructing this interval, the standard error (S.E.) is $\sqrt{\text{M.S.E.} + \text{S.E. (Group Size=24)}}$, where M.S.E. is the mean squared error from the regression. The critical value from the $t$ distribution with 5 degrees of freedom is 2.015.

29 Recall the prices with six and 12 participants are significantly higher than the workable competition benchmark. The result with 24 participants is higher than that benchmark, but the difference is not significant.
$54 as shown in Table 2. It is also significantly higher than the workable competition benchmark of $59.40.

Hypothesis 5 held that reducing antitrust enforcement or changing policy from Category Two to Category Three would raise equilibrium prices above competitive levels, but below the pure monopoly price. Technically, this hypothesis is supported. The result of $99.99 for 24 participants is significantly above the purely competitive price ($54), and also below (by 1 cent) the pure monopoly price cap of $100.

The last hypothesis (H6) correctly anticipated that with a Category Four framework and 24 suppliers, results would be at the pure monopoly price, at the price cap of $100.

The Herfindahl Hirschman Index (HHI) is also shown in Table 1 for each participant size group. It has been used as a benchmark in analyzing competitiveness. For example, the Department of Justice may use this index as one factor in evaluating potential workable competition. As HHI values pass below 1000 they suggest a greater likelihood of competition. In these experiments, however, even the largest group of 24 participants (HHI=417) was able to exercise market power in Experiments 3–6.

5. Conclusion

Three observations qualify the extension of these research findings to policy for actual power markets. First, a different sequence of experiments might lead to different market outcomes for each experiment. For example, if the market size experiments had been sequenced in the reverse order, proceeding from 24 to 12 to 6 participants, the mean prices may have been lower in all three experiments. Second, actual power markets experience scheduled and unscheduled outages, variable load pockets, demand response to price variability, reserve requirements and markets, and offer supply curves which may at times be intentionally lower than those which suppliers believe would create maximum profit. These real market conditions may tend to result in lower market prices than observed in these experiments.

A final observation qualifies interpretation of the results. The participants were always the same 24 individuals, from a graduate class studying restructured markets. They may be said to be in preparation to becoming relevant professionals for actual merchant traders and generators in power markets. We would not expect the results here to be necessarily the same for participants with less knowledge of these markets.

However, assuming the participants are indicative of the potential results of expert traders in actual power markets, the results here suggest that markets with 6, 12, or 24 suppliers can experience the exercise of market power, this in a context more restrictive than current antitrust policy. (As expected, our experimental market results exhibited generally lower prices as the number of suppliers increased.) In addition, as antitrust requirements were relaxed, results with a 24-participant market approached that expected of a monopoly.

While we have noted three qualifications to the interpretation of these results, they would nevertheless seem to give emphasis to the importance of market structure and antitrust policy as factors affecting price outcomes in restructured power markets.

The restructuring of power markets has been part of the deregulation movement of the past two decades. The development of voluntary green marketing of renewable energy, and the growth in interest in marketable permits in pollution emissions have also been integral parts of the movement. As restructuring experienced difficulties, California and New York began to consider supplementing their environmental policy with fixed and growing requirements for renewable energy. Traditionally, the ISOs have not participated in monitoring or scheduling pollution emissions or renewable energy generation. As restructuring continues to evolve in power marketing, we may also consider the likelihood of continued evolution of policies related to renewable generation and pollution emissions.

---

30 The HHI is calculated as the sum of squares of market shares. The maximum HHI value for 100% control is 10,000. The minimum HHI value for a very large number of small suppliers approaches zero.
31 See Viscusi op cit., p. 148.
32 New work with PowerWebIV is addressing some of these issues.

Appendix A. Sample offer instructions, submission, and results pages in PowerWeb

Experiment 1.

Uniform price auction with stochastic load (no price response).

You are one of six suppliers in an electricity market. Each supplier owns 100 MW of capacity, divided into five blocks. Offers to sell these blocks can be submitted into an auction. An ISO selects the least expensive combination of offers to meet the system load and determines the market clearing price (last-accepted-offer) paid to all successful offers. For each period, you will be given a forecast of the system load. The actual load is uncertain but it falls into the range of Forecast\(\pm 20\) MW. When actual load is above 500 MW, some of your capacity is essential to meet load. The chances of load being above or below the forecast are the same.

The operating costs of your capacity have two components. The first is the operating cost per MWh for a capacity that is dispatched. The second is a fixed stand-by cost of $5 per MWh for submitting an offer. Hence, stand-by costs are paid when a block is offered into the market even if it is not dispatched. Withholding blocks from the auction is the only way to avoid stand-by costs for those blocks (the offer submission page for PowerWeb has check boxes for withholding blocks). If the total capacity offered into the auction is less than the actual load, the ISO recalls enough additional capacity to meet load. Recalled capacity is selected at random from the blocks that were withheld from the auction. A recall cost of $10 per MWh must be paid for the entire capacity of any block recalled, as well as the operating cost for the actual recalled quantity purchased.

The amount of time you have to review the results from the previous period and make your offer is limited as shown below. If you do not submit your offer within the allotted time, your offer from the previous period will be automatically submitted for you.

Your objective is to maximize your earnings over a series of 40 periods.
